A dissertation submitted to the University of Cambridge
for the degree of Doctor of Philosophy

Abstract

This thesis describes the optimisation of the calorimeter design for collider experiments at the future Compact Linear Collider (CLIC) and the International Linear Collider (ILC). The detector design of these experiments is built around high-granularity Particle Flow Calorimetry that, in contrast to traditional calorimetry, uses the energy measurements for charged particles from the tracking detectors. This can only be realised if calorimetric energy deposits from charged particles can be separated from those of neutral particles. This is made possible with fine granularity calorimeters and sophisticated pattern recognition software, which is provided by the PandoraPFA algorithm. This thesis presents results on Particle Flow calorimetry performance for a number of detector configurations. To obtain these results a new calibration procedure was developed and applied to the detector simulation and reconstruction to ensure optimal performance was achieved for each detector configuration considered.

This thesis also describes the development of a software compensation technique that vastly improves the intrinsic energy resolution of a Particle Flow Calorimetry detector. This technique is implemented within the PandoraPFA framework and demonstrates the gains that can be made by fully exploiting the information provided by the fine granularity calorimeters envisaged at a future linear collider.

A study of the sensitivity of the CLIC experiment to anomalous gauge couplings that effect vector boson scattering processes is presented. These anomalous couplings provide insight into possible beyond standard model physics. This study, which utilises the excellent jet energy resolution from Particle Flow Calorimetry, was performed at centre-of-mass energies of 1.4 TeV and 3 TeV with integrated lumi-

nosities of 1.5ab^{-1} and 2ab^{-1} respectively. The precision achievable at CLIC is shown to be approximately one to two orders of magnitude better than that currently offered by the LHC.

Finally, a study into various technology options for the CLIC vertex detector is described.

Declaration

This dissertation is the result of my own work, except where explicit reference is made to the work of others, and has not been submitted for another qualification to this or any other university. This dissertation does not exceed the word limit for the respective Degree Committee.

Andy Buckley

Acknowledgements

Of the many people who deserve thanks, some are particularly prominent, such as my supervisor...

Preface

This thesis describes my research on various aspects of the LHCb particle physics program, centred around the LHCb detector and LHC accelerator at CERN in Geneva.

For this example, I'll just mention Chapter ?? and Chapter ??.

Chapter 1

Capacitively Coupled Pixel Detectors for the CLIC Vertex Detector

“There, sir! that is the perfection of vessels!”

— Jules Verne, 1828–1905

1.1 Introduction

Successful identification of heavy-flavour quarks and tau-leptons relies upon precise reconstruction of the secondary displaced vertices produced in the decay of these particles as well as accurate association of the daughter tracks to those vertices. To achieve this for the CLIC experiment very high spatial resolution, of approximately 3 μm and good geometric coverage extending to low θ values are essential. The vertex detector must also have a low material budget, less than $0.2 X_0$ per layer, as to not impact the performance of the other sub detectors and a low occupancy, aided by time-tagging to an accuracy of 10 ns, to counteract the high beam-induced backgrounds found near the impact point.

There are no commercially available technology options that fulfil all the criteria for the vertex detector, which had led the CLIC experiment to consider a variety of new technology options. The focus of this chapter is the use of high voltage complementary metal-oxide-semiconductor (HV-CMOS) active sensors coupled to a separate readout ASIC for the CLIC vertex detector.

Figure 1.1: HV-CMOS diagram.

1.1.1 HV-CMOS

There are two classifications for pixel detectors; hybrid detectors where a passive sensor is bump-bonded to a separate readout chip and fully integrated where the collection diode is built upon the same wafer as the readout circuitry. Both of these technology options find the CLIC experimental conditions extremely challenging. Hybrid technologies struggle to achieved both the radiation tolerance and the functionality in the readout circuitry, while fully integrated circuits have too slow readout times due to limitations on the applied bias voltage.

HV-CMOS is adapted to the CLIC experimental conditions as the n-MOS and p-MOS transistors forming the integrated amplifier (or generic in-pixel logic operations in general) for collecting the signal are embedded within a deep n-well, as shown in figure 1.1. This acts as both the collection diode as well as providing shielding to the circuitry from the beam induced radiation. With the integrated circuitry shielded from the p-substrate it becomes possible to apply a large bias voltage to the substrate to widen the depletion region meaning that the main part of any signal deposited in the detector will be transferred via drift as opposed to diffusion, which provides the fast readout times required by the CLIC experiment.

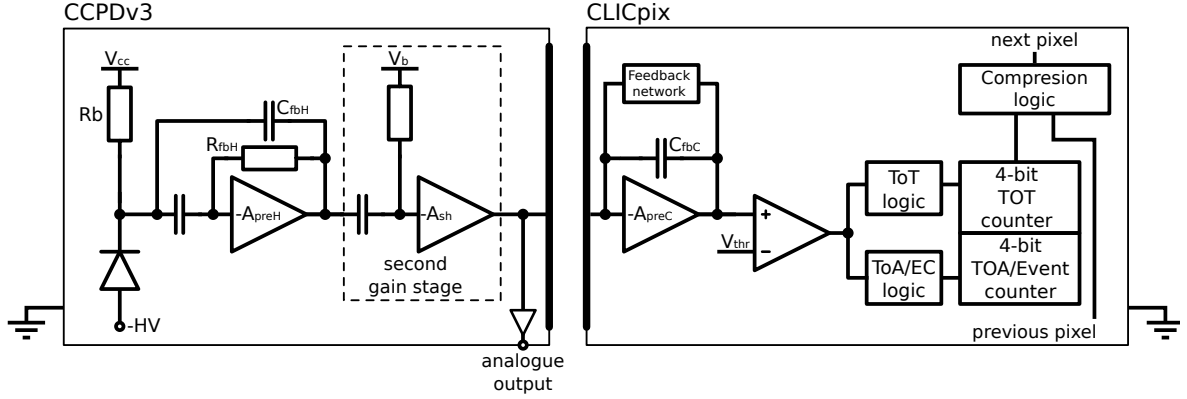

Figure 1.2: Schematic of CCPDv3 and CLICpix pixels.

HV-CMOS devices are strong candidates for the CLIC vertex detector, however, they do have limitations such as noise from interference between the n and p doped wells of the n-MOS and p-MOS transistors that sit within the deep n well. This noise will grow with the number of n-MOS and p-MOS devices on the wafer and so ultimately restricts the complexity of the in-pixel operations that can be performed. There are also topological difficulties such as the difficulty of applying the CMOS process to all sizes and the fact that the deep n well does not occupy the full space of the pixel.

To minimise the material budget for the vertex detector, the pixels used are designed to be as thin as possible. This means the signal from the HV-CMOS will be small as the depletion region will be thin. To counter this, in-pixel signal amplification was applied to the HV-CMOS devices, as shown in figure 1.2. This increases the signal going to the readout ASIC, which also counteracts the intrinsically small capacitance between the HV-CMOS and readout ASIC.

1.1.2 CLICpix

The readout ASIC in this study is the CLICpix, which is a charge integrating amplifier connected to a discriminator as shown in figure 1.2. The output to this discriminator is then used as the input for further logic operations that record the magnitude, using a Time over Threshold (ToT) measurement, and time of arrival of the collected charge.

Figure 1.3: Schematic of alignment of CCPDv3 and CLICpix sensors studied in this analysis. The red dotted line represents the CCPDv3 and the solid black line represents the CLICpix. From left to right; centred pixels, 1/4 offset ($6.25 \mu\text{m}$) and 1/2 offset ($12.5 \mu\text{m}$).

1.1.3 Capacitive Coupling

Solder bump-bonding is the typical method that is used for connecting active pixel sensors to the readout ASIC, however, the solder adds to the thickness of the sensor significantly as well as raising the cost. A viable alternative to this procedure is the replacement of the bump-bonding with a thin uniform layer of glue that forms a capacitive connection between the active pixel and readout ASIC. The mechanical tolerances on the alignment of the active pixel sensor and readout ASIC when applying this glueing procedure are the focus of this study.

1.2 Construction

While replacing solder bump-bonding with a thin layer of glue in the construction of the sensors for the vertex detector offers benefits, such as reductions in the material budget and cost, the manufacturing procedure could lead to misalignments between the active pixel sensor and the readout ASIC. To determine the impact of these misalignments a number of sensors were constructed using the glueing procedure that contained offsets between the HV-CMOS and CLICpix, as shown in figure 1.3. A table 1.1 contains a summary of all the samples used in this study.

The pitch of the pixels produced was $25 \mu\text{m}$ and the matrix size was 64×64 . The full details of the glueing process can be found here (CERN NOTE CITE) along with a study into the absolute precision of the manufacturing procedure. It was found that for devices constructed in an identical fashion to those considered here, the glue layer thicknesses were less than $1 \mu\text{m}$ and the precision on the pixel positioning was less than $0.5 \mu\text{m}$.

1.3 Device Characterisation

This section describes the electrical tests that were performed on the sensor designed to determine the properties of the HV-CMOS and CLICpix.

1.3.1 CLICPix Calibration

Experimental Setup

A radioactive source, Sr^{90} , calibration that was applied to the sensors is presented here. In this procedure the unstable Sr^{90} undergoes β^- decay to form Y^{90} . The Y^{90} , as it too is unstable, undergoes β^- decay to form Z^{90} , which is stable. Each β^- decays produce an e^- and a $\bar{\nu}_e$, and it is the e^- that are used to test the sensitivity of the sensor. The Sr^{90} source used had an activity of 29.6 MBq.

This radioactive source was positioned directly on top of the sensors and measurements were made of both the ToT output from the CLICpix and the HV-CMOS analogue signal for individual pixels on the sensor. The on-pixel event counter was used to veto all events where multiple hits occurred within the time window for a given event.

The HV-CMOS analogue output has a DC output of ≈ 1.15 V and saturation occurs around a signal height of 700 mV. Examples of the HV-CMOS output can be found in figure 1.4.

Figure 1.4: HV-CMOS voltage as a function of time for pulses created by radioactive Sr^{90} source.

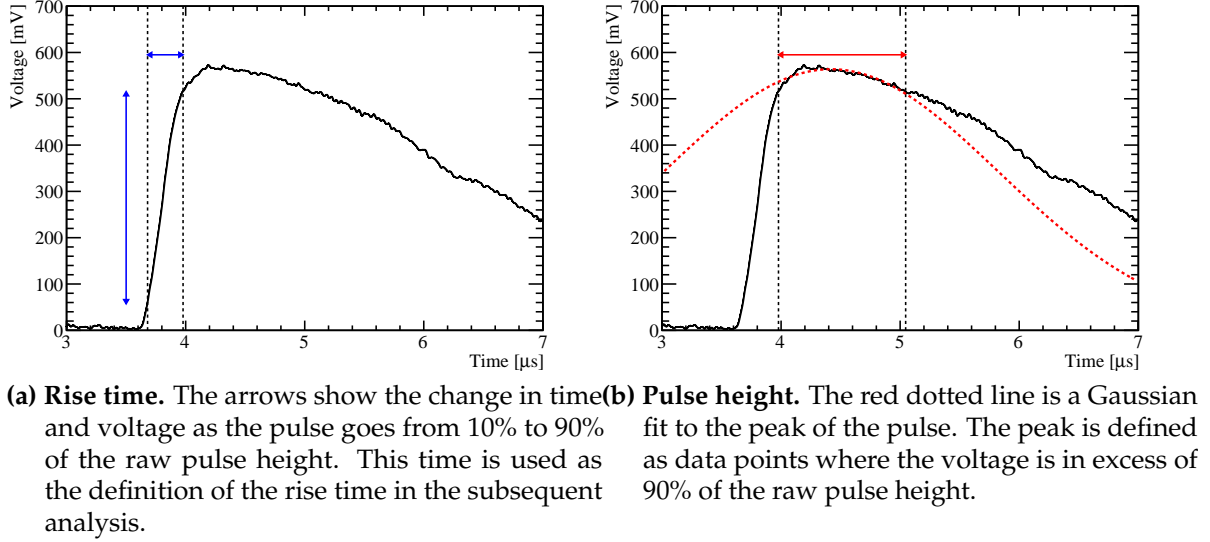

Figure 1.5: Analysis of HV-CMOS voltage as a function of time for pulses created by radioactive Sr^{90} source.

Analysis

The quantities of interest related to the HV-CMOS output are the pulse height and a rise time. The offset voltage was subtracted from the HV-CMOS analogue output and the pulse height inverted before the following analysis was applied.

The pulse height was taken as the mean of a Gaussian fit to the peak of the HV-CMOS output voltage distribution. Such peaks were defined as the data points set that were at or above 90% of the raw peak height, the maximum voltage change recorded. The application of a Gaussian fit provides a more robust metric for categorising the pulse height that is not dependant on minor fluctuations in the voltage. The rise time was calculated as the time taken for the voltage to go from 10% to 90% of the raw peak height. This definition also makes the rise time metric more robust against fluctuations changing the absolute peak height. Examples of the calculation of these metrics for a given pulse are shown in figure 1.5.

For each device the HV-CMOS pulse output was recorded for 15 pixels running along one edge of the 64×64 matrix. In the subsequent section the mean ToT and pulse height are plotted by first binning the distribution, from all pixels considered, of either ToT or rise time against pulse height using bins of 0.25 mV. Then the mean of

the variable of interest is plotted for each bin. The error bars shown in the following section correspond to the standard deviation of the bin contents for each bin.

Results

1.3.2 Cross Couplings

ToT on adjacent cells vs pulse heights. No charge sharing apparent except for SET16. Possible issues with manufacturing other offset samples as some charge sharing is expected.

1.3.3 Test Pulse Calibration

Inject pulse height of fixed size directly into CLICPix and record ToT. This cannot be done for the HV-CMOS due to the device construction preventing getting to the relevant input to the HV-CMOS. Plots of average ToT vs pulse height, describe surrogate function fit and column structure.

1.4 Test Beam Analysis

1.4.1 Test Beam Area

Description of test beam, site and telescope.

1.4.2 Efficiency

- Description of masks and why they need to be applied.
- Alignment description.
- Efficiency calculations and conclusions.
